Abstract

Object identification—the task of deciding that two observed objects are in fact one and the same object—is a fundamental requirement for any situated agent that reasons about individuals. Object identity, as represented by the equality operator between two terms in predicate calculus, is essentially a first-order concept. Raw sensory observations, on the other hand, are essentially propositional—especially when formulated as evidence in standard probability theory. This paper describes patterns of reasoning that allow identity sentences to be grounded in sensory observations, thereby bridging the gap. We begin by defining a physical event space over which probabilities are defined. We then introduce an *identity criterion*, which selects those events that correspond to identity between observed objects. From this, we are able to compute the probability that any two objects are the same, given a stream of observations of many objects. We show that the *appearance probability*, which defines how an object can be expected to appear at subsequent observations given its current appearance, is a natural model for this type of reasoning. We apply the theory to the task of recognizing cars observed by cameras at widely separated sites in a freeway network, with new heuristics to handle the inevitable complexity of matching large numbers of objects and with online learning of appearance probability models. Despite extremely noisy observations, we are able to achieve high levels of performance. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Object identification—the task of deciding that two observed objects are in fact one and the same object—is a fundamental requirement for any situated agent that reasons about individuals. Our aim in this paper is to establish the patterns of reasoning involved in object identification. To avoid possibly empty theorizing, we couple this investigation with a real application of economic significance: identification of vehicles in freeway traffic. Each refinement of the theoretical framework is illustrated in the context of this application. We begin with a general introduction to the identification task. Section 2 provides a Bayesian foundation for computing the probability of identity. Section 3 shows how this probability can be expressed in terms of appearance probabilities, and Section 4 describes our implementation. Section 5 presents experimental results in the application domain. Related work is discussed in Section 6.

1.1. Conceptual and theoretical issues

The existence of individuals is central to our conceptualization of the world. While *object recognition* deals with assigning objects to categories, such as 1988 Toyota Celicas or adult humans, *object identification* deals with recognizing specific individuals, such as one's car or one's spouse. One can have specific relations to individuals, such as ownership or marriage. Hence, it is often important to be fairly certain about the identity of the particular objects one encounters.

Formally speaking, identity is expressed by the equality operator of first-order logic. Having detected an object C in a parking lot, one might be interested in whether $C = \text{MyCar}$. Because mistaken identity is always a possibility, this becomes a question of the *probability of identity*: what is

$$P(C = \text{MyCar} \mid \text{all available evidence})?$$

There has been little work on this question in AI.² The approach we will take (Section 2) is the standard Bayesian approach: define an event space, assign a prior, condition on the evidence, and identify the events corresponding to the truth of the identity sentence. The key step is the last, and takes the form of an *identity criterion*. Once we have a formula for the probability of identity, we must find a way to compute it in terms of quantities that are available in the domain model. Section 3 shows that one natural quantity of interest is the *appearance probability*. This quantity, which covers diverse domain-specific phenomena ranging from the effects of motion, pose, and lighting to changes of address of credit applicants, seems to be more natural and usable than the usual division into sensor and motion models, which require calibration against ground truth.

1.2. Application

The authors are participants in *Roadwatch*, a major project aimed at the automation of wide-area freeway traffic surveillance and control [7]. Object identification is required

² In contrast, reasoning about category membership based on evidence is the canonical task for probabilistic inference. Proposing that *MyCar* is just a very small category misses the point.

Fig. 1. Images from upstream (a) and downstream (b) surveillance cameras roughly two miles apart on Highway 99 in Sacramento, California. The boxed vehicle has been identified at both cameras.

Fig. 2. Overall design of our traffic surveillance system. The video streams are processed at each camera site by vehicle tracking software running on customized parallel hardware. The resulting streams of chronologically ordered vehicle reports are sent to the TMC (Traffic Management Center). The TMC uses these reports to determine when a vehicle detected at one camera has reappeared at another. These matches are used to build up a path for each vehicle as it travels through the freeway network. The set of paths can be queried to compute link travel times and O/D counts as desired. The output of the system is a traffic information display, updated in real time for use by traffic operations managers or by individual drivers.

for two purposes: first, to measure *link travel time*—the actual time taken for traffic to travel between two fixed points on the freeway network; and second, to provide *origin/destination (O/D) counts*—the total number of vehicles traveling between any two points on the network in a given time interval. The sensors used in this project are video cameras placed on poles beside the freeway (Fig. 1). The overall system design is shown in Fig. 2. In addition to the real surveillance system, we also implemented a complete microscopic freeway simulator capable of simulating several hundred vehicles in realistic traffic patterns. The simulator includes virtual cameras that can be placed anywhere on the freeway network and that transmit real-time streams of vehicle reports to the traffic management center (TMC). The reported data can be corrupted by any desired level of

noise. We found the simulator to be an invaluable tool for designing and debugging the surveillance algorithms.

Obviously, a license-plate reader would render the vehicle identification task trivial, but for political and technical reasons, this is not feasible. In fact, because of very restricted communication bandwidth, the vehicle reports sent to the TMC can contain only about one hundred bytes of information. In addition, the measurements contained in the reports are extremely noisy, especially in rainy, foggy, and night-time conditions. Thus, with thousands of vehicles passing each camera every hour, there may be many possible matches for each vehicle. This leads to a combinatorial problem—finding most likely consistent assignments between two large sets of vehicles—that is very similar to that faced in *data association*, a form of the object identification problem arising in radar and sonar tracking. Section 6 explores this connection in more detail. We adopt a solution from the data association literature, but also introduce a new “leave-one-out” heuristic for selecting reliable matches. This, together with a scheme for online learning of appearance models to handle changing viewing and traffic conditions, yields a system with performance good enough for practical deployment (Section 5).

2. Inferring identity from observations

This section shows how the probability of identity can be defined in terms of physical observations and events. We begin with the formal framework and then illustrate it in the traffic domain.

2.1. Formal Bayesian framework

Let O be a random variable whose domain is the set of complete observation histories. That is, any particular value of O might correspond to the complete set of observations of objects made by some agent: $O = \{o_1, \dots, o_n\}$. Let o_a and o_b be two specific observations made, which we may think of as having been caused by objects a and b .³ Informally, we may write the probability of identity of a and b as $P(a = b \mid O = \{o_1, \dots, o_n\})$.⁴

To make this probability evaluable, we define an event space $S = \langle H_1, \dots, H_N \rangle$, where each H_k is a random variable denoting the “life history” of the k th object in the universe, and each event is an N -tuple specifying the life history of all N objects. We can think of the index k as an invisible “object identification number”. We impose a prior distribution $P(S)$, with the restriction that the prior is exchangeable, i.e., invariant under any permutation of

³ For the purposes of this paper, we will assume that each observation corresponds to exactly one physical object. This assumption can be relaxed, at the cost of introducing into the theory the mechanism whereby objects generate observations.

⁴ One is tempted to write this as $P(a = b \mid o_1, \dots, o_n)$, i.e., to condition on a conjunction of the “positive” observations. However, conditioning on the positive observations is not the same as conditioning on both positive observations and negative observations—that is, observations of no vehicles at a given time and place. The temptation therefore reflects a natural “semi-closed-world” assumption: one assumes that the stated positive observations are all that have been made in the past, and that all other observations were negative. Obviously, one does not make this assumption regarding the future.

object indices. Also, we will use the notation $o_i \in H_k$ to mean that observation o_i was generated by the k th object.

Now the key step is to provide an *identity criterion* to select those events corresponding to a and b being the same object. We write this as

$$a = b \iff \bigvee_k [(o_a \in H_k) \wedge (o_b \in H_k)].$$

That is, the two observed objects are the same if each observation was generated by the life history of the same object. This is the basic step in relating propositional observations to identity sentences.

Since the propositions in this disjunction are mutually exclusive, we have

$$P(a = b \mid O) = \frac{P(a = b, O)}{P(O)} = \frac{1}{P(O)} \sum_k P((o_a \in H_k) \wedge (o_b \in H_k), O).$$

Conditioning on the event space S yields

$$P(a = b \mid O) = \frac{1}{P(O)} \int \sum_k P(o_a, o_b \in H_k, O \mid s) P(s) ds$$

where $o_a, o_b \in H_k$ is shorthand for $(o_a \in H_k) \wedge (o_b \in H_k)$. Finally, we expand $P(o_a, o_b \in H_k, O \mid s)$ to obtain

$$P(a = b \mid O) = \frac{1}{P(O)} \int \sum_k P(O \mid o_a, o_b \in H_k, s) P(o_a, o_b \in H_k \mid s) P(s) ds. \quad (1)$$

In this way, we express the probability of identity in terms of the probability of observations given events. We now make this framework more concrete in the context of the traffic domain.

2.2. Identity in the traffic domain

The basic vehicle identification task involves two cameras on a freeway, one upstream and one downstream. The TMC monitors a vehicle's progress by matching the appropriate upstream observation of the vehicle with the appropriate downstream observation. It is natural to keep the observation history O separated in two parts, U (observations by upstream camera u) and D (observations by downstream camera d). Each observation $o_i^u \in U$ of vehicle i is a pair (r_i^u, f_i^u) , where r_i^u includes the location of the vehicle and the time of observation, while f_i^u corresponds to observed values of intrinsic features of the vehicle, such as color and size. The same holds for observation $o_j^d \in D$ of vehicle j . It is reasonable to assume that each r is unique, since a vehicle cannot be in two places at once, nor can two vehicles be in the same place at once.

H_k can be thought of as a *trajectory* for the k th vehicle, specifying its position as a function of time. The identity criterion for observed vehicles a and b now becomes

$$a = b \iff \bigvee_k [(r_a^u \in H_k) \wedge (r_b^d \in H_k)].$$

Fig. 3. Time-space diagrams showing two possible events in the two-car universe, given observations o_a^u and o_b^d (and no other observations). In (a), we have $a = b$, while in (b), we have $a \neq b$.

To illustrate Eq. (1), consider the simplified case where the universe contains exactly two vehicles of similar appearance, each moving at constant velocity along the same road. Two reliable cameras, located at y_u and y_d , make observations whenever vehicles pass by. From time $t = 0$ to $t = T$, the observation history O consists of $U = \{o_a^u\}$ recorded at t_a and $D = \{o_b^d\}$ recorded at t_b . The event space $S = \langle H_1, H_2 \rangle$ therefore ranges over all possible trajectories for two vehicles; these can, in turn, be defined by the random variables $\langle y_1, v_1 \rangle$ and $\langle y_2, v_2 \rangle$, where y_1 and y_2 are the positions of the vehicles at time t_a and v_1 and v_2 are the velocities. Fig. 3 shows two possible events consistent with the observations—one where $a = b$ and one where $a \neq b$.

It turns out to be easiest to compute the probability of identity from the ratio

$$\frac{\int_{s \in S} P(a = b, O | s) P(s) ds}{\int_{s \in S} P(a \neq b, O | s) P(s) ds}$$

since the $P(O)$ term in Eq. (1) cancels. Suppose now that $y_d - y_u$ is 2000 meters, and that $t_b - t_a$ is 100 seconds. Furthermore, suppose $P(S)$ is such that y_1 and y_2 are independently and uniformly distributed in the range $[y_u, y_d]$, and v_1 and v_2 are independently and uniformly distributed in the range $[10 \text{ m/s}, 40 \text{ m/s}]$. Then $P(s)$ is constant over the range of integration and the above ratio is given by

$$\frac{\int_{y_u}^{y_d - 10(t_b - t_a)} \int_{10}^{(y_d - y_2)/(t_b - t_a)} dv_2 dy_2}{\int_{10}^{(y_d - y_2)/(t_b - t_a)} dv_1 \int_{y_u}^{y_d - 10(t_b - t_a)} dy_2} = \frac{1}{2},$$

hence $P(a = b | O) = 1/3$.

3. Appearance models

The previous section showed how to express the probability of identity in terms of the probability of observations given events. Some domains, including traffic surveillance, involve observation sets that contain initial observations of objects as well as subsequent

observations of objects. In these situations, appearance probabilities, which define how objects observed at some point in the past can be expected to appear at some point in the future, seem to provide a more usable model than standard motion and sensor models. In this section, we show how to express Eq. (1) in terms of appearance probabilities and describe the specific appearance probabilities used in the vehicle identification domain.

3.1. Identity in terms of appearance probabilities

Suppose we are given observation history $O = U \cup D$, where U consists of initial observations of objects, and D consists of subsequent observations of objects. Keeping these sets separate in Eq. (1) gives the following for $P(a = b \mid U, D)$:

$$\frac{1}{P(U, D)} \int \sum_k P(U, D \mid o_a, o_b \in H_k, s) P(o_a, o_b \in H_k \mid s) P(s) ds.$$

Expanding $P(U, D \mid o_a, o_b \in H_k, s)$ yields

$$\begin{aligned} \frac{1}{P(U, D)} \int \sum_k P(D \mid U, o_a, o_b \in H_k, s) P(U \mid o_a, o_b \in H_k, s) \\ \times P(o_a, o_b \in H_k \mid s) P(s) ds. \end{aligned}$$

At this point, we define a new event space Ω , which is a coarsening of S . First, we need some new terms: a *matching* is simply a pairing indicating that two observations were generated by the same object. For example, the matching (a, b) indicates that the same object generated o_a and o_b . Given a set of initial observations and a set of subsequent observations, an *assignment* is a set of matchings for every observation in each set. The *assignment space* Ω is an event space that ranges over the space of possible assignments. It thus divides the space S into subsets of events, such that each subset is relatively *homogeneous* if we condition on the observations—because each subset then effectively specifies that starting point and ending point of each vehicle's trajectory.

Summing over only those assignments ω that satisfy the identity criterion for a and b gives

$$P(a = b \mid U, D) = \frac{1}{P(U, D)} \sum_{\omega \in \Omega: (a, b) \in \omega} P(D \mid U, \omega) P(U \mid \omega) P(\omega).$$

Since the principle of exchangeability requires a uniform prior over Ω , and since $P(U \mid \omega)$ is constant given no information about the observations to which the observations in U correspond, these constant terms can be grouped outside of the summation along with the normalization constant $P(U, D)^{-1}$ so that we have

$$P(a = b \mid U, D) = \alpha \sum_{\omega \in \Omega: (a, b) \in \omega} P(D \mid U, \omega).$$

Our final assumption is that the probability of a specific subsequent observation, given a specific initial observation and a matching between the two observations, is independent of

the other observations and matchings. (This assumption is discussed further below.) Hence, we can factor $P(D \mid U, \omega)$ into the product of the individual probabilities as follows:

$$P(D \mid U, \omega) = \prod_{(i,j) \in \omega} P(o_j^d \mid o_i^u, i = j). \quad (2)$$

In this expression, $P(o_j^d \mid o_i^u, i = j)$ is an *appearance probability*, the probability that an object that initially generated observation o_i^u subsequently generated observation o_j^d . We will write this as $P(o^d \mid o^u)$ where no confusion is possible. It is important to note that the appearance probability is *not* the probability that $i = j$.

Eq. (2) can be substituted into the identity equation to give

$$P(a = b \mid U, D) = \alpha \sum_{\omega \in \Omega: (a,b) \in \omega} \prod_{(i,j) \in \omega} P(o_j^d \mid o_i^u, i = j). \quad (3)$$

This is the basic equation we will use for identifying objects. Notice that if there are n candidate objects for matching, then the set $\{\omega \in \Omega: (a, b) \in \omega\}$ contains $(n - 1)!$ possible assignments consistent with $a = b$. It can be shown that this complexity is unavoidable—our task essentially involves computing the permanent of a matrix—so our implementation will be based on a heuristic approximation.

To ground this discussion, we will now discuss the specific observed features and appearance probability models used in the traffic domain.

3.2. Observed features for traffic

When a certain camera c observes some vehicle i , it generates a vehicle report consisting of various *features*. Thus, the observation o_i^c in our system is a vector of features. Currently, we use the features shown in Table 1.

Table 1
Features used in vehicle observation reports

Name	Description
t	Time of observation
x	Lane position (1, 2, 3, etc.)
y	Distance along lane
\dot{x}	Lateral velocity
\dot{y}	Forward velocity
w	Vehicle width
l	Sum of vehicle length and height
h	Mean vehicle color hue
s	Mean vehicle color saturation
v	Mean vehicle color value
C	Histogram of color distribution over vehicle pixels

The matching algorithm is designed to be independent of the specific features used; new features of arbitrary complexity, informativeness, and noise level can be added without changing the algorithm. In particular, it is possible to use direct matching of vehicle images as an additional feature as long as the communication bandwidth is available.

3.3. Appearance probabilities for traffic

The appearance probability is currently treated as the product of the following independent models:

- lane (x): discrete distribution $P(x^d | x^u)$;
- size (w, l): multivariate Gaussian

$$P(w^d, l^d | w^u, l^u) = N_{\mu_{w,l}, \Sigma_{w,l}}(w^d - w^u, l^d - l^u);$$

- color (h, s, v): multivariate Gaussian

$$P(h^d, s^d, v^d | h^u, s^u, v^u) = N_{\mu_{h,s,v}, \Sigma_{h,s,v}}(h^d - h^u, s^d - s^u, v^d - v^u);$$

- arrival time (t): univariate Gaussians conditioned on upstream and downstream lane

$$P(t^d | t^u, x^d, x^u) = N_{\mu_t^{x^d, x^u}, \sigma_t^{x^d, x^u}}(t^d - t^u).$$

The arrival time model is particularly important, since it drastically reduces the number of vehicle pairs that are considered to be plausible matches. The parameters

$$\mu_t^{x^d, x^u} \quad \text{and} \quad \sigma_t^{x^d, x^u}$$

represent the mean and standard deviation of the predicted link travel time for cars that start upstream in lane x^u and end up downstream in lane x^d . This allows the system to accurately model, for example, the fact that cars in the carpool lane travel faster than cars in other lanes.

Our assumption that vehicle trajectories are independent, used in Eq. (2), would make little sense for traffic, were it not for the fact that the appearance probability submodel for arrival time is parameterized by $\mu_t^{x^d, x^u}$, the current average travel time for the link. Clearly, the trajectories of consecutive cars in a stream of heavy traffic are highly correlated rather than independent, but we subsume most of this correlation in the current average travel time. The assumption of independence given average travel time is identical to the assumption made by Petty et al. [8], whose work is discussed in Section 6.

In examining the empirical distributions for the appearance probability, we were surprised by the level of noise and lack of correlation in measurements of the same feature at two different cameras. Some features, such as color saturation and vehicle width, appear virtually uncorrelated. In all, we estimate that the size and color features provide only about 3–4 bits of information.

3.4. Online learning of appearance models

Because traffic and lighting conditions change throughout the day, our system uses online (recursive) estimation for the appearance probability model parameters. As new

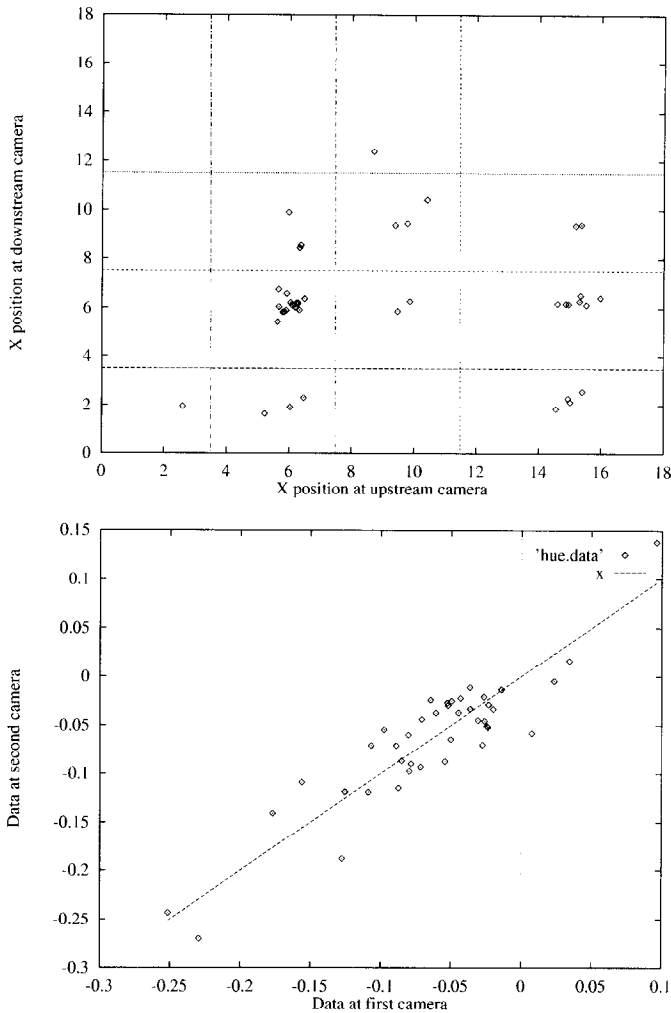

Fig. 4. *Top*: diagram showing observed upstream and downstream x -position data for a sample of 41 matched vehicles from the Mack Road and Florin Road cameras. The horizontal axis corresponds to upstream x -position and the vertical axis corresponds to downstream x -position. Each marked point corresponds to a single matched vehicle. Lane dividers are shown as horizontal and vertical lines. For example, 13 vehicles are observed upstream in lane 4 (onramp, highest x values), of which 7 are observed downstream in lane 2 (middle lane), indicating that $P(x^d = 2 \mid x^u = 4) \approx 0.54$. *Bottom*: upstream and downstream hue data for a sample of 25 matched vehicles. The line $y = x$ corresponds to perfect reproduction of hue at the two cameras. The appearance probability for color, which includes hue, saturation, and value components, is modeled as a multivariate Gaussian.

matches are identified by the vehicle matcher, the parameters are updated based on the observed feature values at the upstream and downstream sites. Fig. 4 shows a sample set of x values for matched vehicles, from which $P(x^d \mid x^u)$ can be estimated, as well as a sample set of hue values for matched vehicles, from which $P(h^d \mid h^u)$ can be estimated. To adapt to changing conditions, our system uses online exponential forgetting. For example, if a

new match is found for a vehicle in lane x^u upstream and lane x^d downstream, with link travel time t , then the mean travel time is updated as follows:

$$\mu_t^{x^u, x^d} \leftarrow \gamma \mu_t^{x^u, x^d} + (1 - \gamma)t.$$

The γ parameter, which ranges from 0.0 to 1.0, controls the effective “window size” over which previous readings are given significant weight.

The above assumes that the match found is in fact correct. In practice, we can never be certain of this. A better motivated approach to model updates would be to weight each update by the probability that the match is correct. An approach that avoids matching altogether is described in Section 6.

4. Matching algorithm

We begin by describing the simplest case, where all vehicles detected at the upstream camera are also detected downstream, and there are no onramps or offramps. We then describe the extension to handle onramps and offramps.

4.1. Matching with full correspondence

The aim is to find pairs of vehicles a and b such that

$$P(a = b \mid U, D) > 1 - \varepsilon$$

for some small ε . We have derived an Eq. (3) for this quantity, under certain independence assumptions, and shown how to compute the appearance probabilities that are used in the equation. As mentioned earlier, the problem that we now face is the intractability of computing the summation involved.

The core of the approach is the observation, due to Cox and Hingorani [5], that a most probable assignment (pairing all n vehicles) can be found in time $O(n^3)$ by formulating the problem as a weighted bipartite matching problem and using any of several well-known algorithms for this task. To do this, we construct an *association matrix* M of appearance probabilities, where each entry

$$M_{ij} = -\log P(o_j^d \mid o_i^u),$$

so that the assignment with least total weight in the matrix corresponds to the most probable assignment, according to Eq. (2).

For our purposes, knowing the most likely assignment is not enough. It can easily happen that some c of the n vehicles are all very similar and fairly close to each other on the freeway—a situation that we call a *clique*. One common example might be cliques of yellow cabs on the freeways leading to major airports. Given a clique of size c , there will be $c!$ assignments all having roughly the same probability as the most probable assignment. Since matches within the clique may be very unreliable, we employ a *leave-one-out* heuristic that “forbids”, in turn, each match contained in the best assignment. For each forbidden match, we measure the reduction in likelihood for the new best assignment. Matches whose forbidding results in a significant reduction are deemed reliable, since this

Upstream	Downstream			
	x	y	off	off
a	$(1 - \alpha)P(o_x o_a)$	$(1 - \alpha)P(o_y o_a)$	α	α
b	$(1 - \alpha)P(o_x o_b)$	$(1 - \alpha)P(o_y o_b)$	α	α
new	$\beta P(o_x)$	$\beta P(o_y)$	1	1
new	$\beta P(o_x)$	$\beta P(o_y)$	1	1

Fig. 5. Extended association matrix for two upstream and downstream observations, showing additional rows and columns to account for entering and exiting vehicles. Each entry will be replaced by its negative logarithmic value before computing the minimum weight assignment.

corresponds to a situation where there appears to be no other reasonable assignment for the upstream vehicle in question.

For example, suppose we have the following association matrix:

Upstream	Downstream		
	x	y	z
a	3.2	2.5	12.7
b	8.5	4.5	4.4
c	7.3	5.0	5.0

Here the best assignment is $\{a = x, b = z, c = y\}$, with a total weight of 12.6. (Notice that $a = y$ is the “closest” match for a , but leaves no good match for the others.) If we forbid $a = x$, the best assignment is $\{a = y, b = z, c = x\}$ with weight 14.2. If the difference between these two weights is greater than some reliability threshold t ,⁵ i.e., if $14.2 - 12.6 > t$, then we accept the $a = x$ match, since no other reasonable choice seems to exist. On the other hand, if we forbid $b = z$, the best assignment has weight 12.7. If $12.7 - 12.6 \leq t$, then we reject $b = z$, since there is another match for b that yields a good overall assignment. By increasing the threshold t , we obtain more reliable matches, i.e., the error rate ε is reduced; however, this reduces the overall number of accepted matches.

4.2. New and missing vehicles

In the general case, vehicles can appear from onramps between the cameras or can disappear onto offramps. (Equivalently, they can fail to be detected at the upstream or downstream camera.) To handle this, we add extra rows and columns to the association matrix. With m upstream and n downstream vehicles, the matrix now has $m + n$ rows and columns to allow for all possibilities. Fig. 5 illustrates the structure of the matrix for

⁵ The value compared with the reliability threshold is the negative logarithm of the relative likelihood of the observations given the best assignment and the observations given the best assignment with a forbidden match.

$m = n = 2$. Here, α is the probability that a vehicle exits the freeway, β is the number of vehicles entering the freeway between the cameras per unit time, and $P(o_i)$ refers to the prior probability of seeing a vehicle with features o_i .⁶ The formulas in the table explain the interesting fact that human observers feel far more confident matching unusual vehicles than typical vehicles: not only is the probability of confusion with other vehicles lower, but the probability that the upstream vehicle exited, only to be replaced by another vehicle of the same unusual appearance, can be discounted because the extra multiplicative $P(o_i)$ factor for an unusual vehicle would be tiny.

5. Results

We tested the vehicle matcher with data from a region-based vehicle tracker on video sequences from the sites in Fig. 1.

On any given run, the number of matches proposed by the vehicle matcher depends on the reliability threshold selected for that run. In the results discussed below, *coverage* refers to the fraction of vehicles observed by both cameras for which matches were proposed, and *accuracy* refers to the fraction of proposed matches that were in fact correct. In general, the coverage goes down as the reliability threshold is increased, but the accuracy goes up.

To verify the accuracy of the matcher, the ground-truth matches were determined by a human viewing the digitized sequences with the aid of a frame-based movie viewer. Since this method required about 3 hours of viewing to match each minute of video, it was used only during the early stages of testing. In subsequent testing, we first ran the matcher on the vehicle report data and then used the frame-based movie viewer to verify whether the suggested matches were correct.

Testing our system involved a start-up phase during which it estimated the appearance probability models online. For the results shown in Fig. 6, we trained our system on a pair of 60-second video sequences and then ran it on the immediately following 60-second sequences. The sequences contained 29 vehicles detected at both cameras, along with over 40 vehicles that either entered or exited the freeway in between the cameras. The resulting accuracy/coverage curve in Fig. 6(a) shows that despite very noisy sensors, the system achieved 100% accuracy with a coverage of 14%, and 50% accuracy with a coverage of 80%. To simulate performance on freeway sections without onramps and offramps, we also tried removing the tracks of entering and exiting vehicles from the data stream. This makes the problem substantially easier: we achieved 100% accuracy with a coverage of 37%, and 64% accuracy with a coverage of 80% (Fig. 6(b)). The boxed vehicles in Fig. 1 show a pair of vehicles correctly matched by our system.

Link travel times between each camera pair are currently calculated by averaging the observed travel times for matched vehicles. These times were accurate to within 1% over a distance of two miles, over a wide range of coverage/accuracy tradeoff points. This suggests that matched vehicles are representative of the traffic flow—that is, the matching process does not select vehicles with a biased distribution of speeds.

⁶ In our implementation, each of these models is learned online; α and β are also specific to individual lanes.

Fig. 6. Sample matching results: the graphs shows accuracy versus coverage for a range of reliability threshold values. A low threshold implies high coverage and low accuracy, while a high threshold implies low coverage and high accuracy. (a) Results for a 60-second video sequence containing 29 vehicles detected at both cameras as well as over 40 entering and exiting vehicles. (b) Results for the same sequence with the tracks of entering and exiting vehicles removed, to simulate performance on freeway sections without onramps and offramps.

6. Related work

The vehicle matching problem is closely related to the traditional “data association” problem from the tracking literature, in which new “observations” (from the downstream camera) must be associated with already-established “tracks” (from the upstream camera). Radar surveillance for air traffic control is a typical application: the radar dish determines an approximate position for each aircraft every few seconds, and each new set of positions must be associated with the set of existing tracks. There is a large literature on data association—typically over 100 papers per year. The standard text is by Bar-Shalom and Fortmann [3], and recent developments appear in [2]. Ingemar Cox [4] surveys and integrates various developments, deriving formulas very similar to those in Fig. 5. Cox’s aim in his review paper is to present the ideas from the data association field to the computer vision and robotics community, where they might be used to resolve problems of identifying visual features seen in temporally separated images by a moving robot. Major differences between our work and “standard” data association include the following:

- (1) Sensor noise and bias are large, unknown, time-varying, site-dependent, and camera-dependent, and sensor observations are high-dimensional.
- (2) In radar tracking, the distance moved by each object between observations is typically small compared to inter-object distances; in freeway traffic, the opposite is true.
- (3) Traffic observations are asynchronous.
- (4) Vehicle trajectories in traffic are highly correlated.

As explained in Section 3, this last problem is dealt with in our approach by conditioning trajectories on the current average link travel time. This is a device that may prove to be useful in many other applications involving the modelling of very large systems using aggregate parameters.

The most closely related work on statistical estimation of travel time is by Petty et al. [8]. They have shown that it is possible to estimate travel times using an “ensemble” matching approach that detects downstream propagation of distinct arrival time patterns instead of individual vehicles. Because it uses only the arrival times, it can operate using data from *loops*—that is, induction coils placed under the road surface that indicate the passage of a vehicle. Using this technique, travel times were estimated accurately over a wide range of traffic conditions. The method is, however, limited to loops that are fairly close together and have no intervening onramps or offramps.

We are currently collaborating with the authors of the “ensemble” approach to develop a system that combines the two approaches and may overcome many of the shortcomings of each. The basic idea, due primarily to Ritov, is to use a Monte Carlo Markov Chain algorithm to approximate the sum over assignments in Eq. (3). The states of the Markov chain are complete assignments and the transitions exchange pairings between two pairs of vehicles. The transition probabilities are defined such that detailed balance is maintained and the fraction of time during which any given state is occupied is proportional to the probability of the corresponding assignment. Hence, the probability of any given proposition (such as $a = b$) can be estimated as the fraction of time spent in states where it is true. Results due to Jerrum and Sinclair [6] show that the Monte Carlo method applied this particular chain gives polynomial-time convergence.

This approach can in fact estimate travel times and O/D counts without ever selecting likely vehicle matches at all: simply compute the average travel time and average O/D counts over all the assignments visited by the chain. Similarly, the appearance probability models can be updated after each transition as if the assignment were correct; in the limit, the updated models will reflect the observed data correctly. Since changing the appearance models changes the transition probabilities of the chain, the process must be iterated until convergence. This is an instance of the EM algorithm, where the hidden variables are the link travel times. We are currently experimenting to see if this approach can be used in a real-time setting where the structure of the Markov chain is continually changing as new vehicles are detected.

7. Conclusions and further work

This paper has described the patterns of reasoning involved in establishing identity from observations of objects. We proposed a formal foundation based on a prior over the space of physical events, together with an identity criterion defining those events that correspond to observations of the same object. In the case of vehicle matching, the events are the different sets of trajectories of vehicles in a given freeway network. When a single trajectory passes through two vehicle observations, that implies that the observations correspond to the same object. This general approach makes it possible to define the probability of identity and to integrate the necessary patterns of reasoning into an intelligent agent.

This research can be seen as another step in the Carnapian tradition that views a rational agent as beginning with uninformative prior beliefs and then applying Bayesian updating throughout its lifetime. The general relationship between perception and the formation of internal models is a subject that needs much more investigation [1].

We showed that the abstract probability of identity can be expressed in terms of measurable appearance probabilities, which define how, when, or where objects that were observed at some point in the past are expected to appear at some point in the future. These appearance probabilities can be learned online to adapt to changing conditions in the environment—such as changing weather, lighting, and traffic patterns.

We have implemented and tested a system for vehicle matching using an efficient algorithm based on bipartite matching combined with a leave-one-out heuristic. Despite very noisy feature measurements from the cameras, our system achieved a high level of accuracy in matching individual vehicles, enabling us to build the first reliable video-based system for measuring link travel times. Although experimental camera data were not available for the system to do so, it is already capable of tracking the path of a vehicle over a sequence of camera sites. Thus, O/D counts for a time period can be computed by examining the complete set of recorded paths during that time period. For successful O/D measurement over a long sequence of cameras, however, we need to improve both matching coverage and the detection rate of the tracking subsystem. We can perform a crude analysis as follows: if the coverage for the vehicle matcher is c , and the matching accuracy is a , and the single-camera vehicle detection rate is p , then the probability that a vehicle is correctly tracked across n sites is $p^n a^{n-1} c^{n-1}$ (assuming independence). Suppose now that $n = 10$. To achieve 90% accuracy in O/D counts, we need $a^9 = 0.9$ or $a \approx 0.988$ as well as a sufficiently high number of tracked vehicles in order to keep sampling error low. The required percentage of vehicles to be tracked across the 10 sites will depend on flow rates and the length of the reporting period. To track, say, 10% of vehicles across 10 sites we need $p^{10} c^9 = 0.1$. Given $p = 0.95$, this means we need $c \approx 0.82$. Currently, simultaneous achievement of 98.8% accuracy and 82% coverage is not feasible. However, we anticipate that improved measurement of features such as width and height would provide dramatic improvement in coverage and accuracy. Other possibilities include selecting a subset of pixels from the rear plane of each vehicle to be used as a match feature.

The patterns of reasoning described here have broad applicability to other domains. For example, the object identification problem occurs in database management, where it is possible that two different records could correspond to the same entity. Thus, US credit reporting agencies record over 500 million credit-using Americans, of whom only about 100–120 million are actually distinct individuals. Applying our approach to this problem could help with maintaining database consistency and with consolidating multiple databases containing overlapping information.
